Our research group is interested in mono- and dinuclear metal complexes that interact with the rare left-handed Z-DNA.[1, 2] The temporary formation of Z-DNA during transcription could be exploited as a new target for rapidly replicating cells. This could lead to a completely novel strategy in the fight against cancer.

We are searching for metal complexes that can discriminate between the prevalent right-handed B-DNA and Z-DNA. The presentation will summarize our recent research efforts, mainly in the area of azamacrocyclic complexes. It will be shown for several cases that the ability to crystallize and study important intermediate and final products was essential for the progress of our research.[3]

In continuation of our investigations on the relative contributions of different factors to the stabilization of divalent Group 14 (E\textsuperscript{14}) compounds, we report here the results of experimental and theoretical studies of a new stable lead(II) complex Pb(SCH\textsubscript{2}CH\textsubscript{2}NH\textsubscript{2})\textsubscript{2} (1). The molecular structure of 1 was studied by single-crystal X-ray diffraction analysis at 100 and 290 K and variable-temperature (93-303 K) Raman spectroscopy in solid state. The electronic structure of 1 was elucidated by quantum-chemical calculations within the DFT approach. The X-ray diffraction study has shown that 1 is a monomer stabilized by two intramolecular coordination N→Pb bonds with the formation of two five-membered rings, both having the usual envelope conformations. In the crystal of 1 at 100 K, the only asymmetrical conformer with the two five-membered rings differing in the positions of the cap-carbon atoms was observed (Fig. 1a). In contrast, at the same conditions the Ge(II) (2) and Sn(II) (3) analogs of 1 have symmetrical structures, in which the conformations of both five-membered rings are identical (Fig. 1b) [1]. However, the X-ray crystal structure analysis at 290 K has revealed that 1 exists both as the asymmetrical and symmetrical conformers in the 7:3 ratio, respectively; the minor symmetrical conformer has the same structure as those of 2 and 3 (Fig. 1c). It is interesting to note that only one of the two five-membered heterocycles in 1 (in the conformation unobserved in 2 and 3) undergoes the transformation upon heating. The most striking feature of the Raman spectra of 1 is a doublet at 885/896 cm\textsuperscript{-1}, which is absent in the spectra of 2 and 3. This doublet evidently reflects the presence of two different conformations of the five-membered rings and is explained by rotational isomerism about the ordinary C-C bond. The reasons for the phenomenon found for 1 are currently under investigation.
