One important challenge in today's solid state chemistry is to be able to conceive materials with particular physico-chemical properties. The possibility of predicting new structures according to a wished property and the faculty to formulate it, is surely a main advantage in the design of new materials.

In the Bi$_2$O$_3$-M$_2$O$_7$-P$_2$O$_5$ ternary systems, on the basis of previous compounds based on 2D-ribbon like units [1][2], we have prepared numerous compounds with an original predictive approach, based either regularly repeating hydrogen-bonded rings propagated by a 2-fold screw axis or alternating hydrogen bonded rings propagated by a centre of inversion. We set out to examine how robust these supramolecular synthons would be under the influence of various molecular interferences. Compounds have been characterised by single crystal and powder X-ray diffraction. Their thermal stability and decomposition behaviour have been studied using Differential Scanning Calorimetry, Thermogravimetry and Hot Stage Microscopy.

Active pharmaceutical ingredients (API) suffer from some disadvantages in the solid state, particularly poor solubility or bioavailability and polymorphism. By making use of crystal engineering concepts to make pharmaceutical co-crystals and pharmaceutical salts, which are hydrogen bonded assemblies between the API and a GRAS (generally-regarded-as-safe) substance, it is possible to increase the water solubility, or to reduce the likelihood of polymorphic behaviour of the API itself. The same supramolecular synthons are observed in amine salts of carboxylic acid containing APIs such as (S)-Buprofen, Diclofenac and Fenofibrate [5]. We have found that these supramolecular synthons are extremely robust but can be switched off under the influence of various molecular interferences. We have also established some principles involving the physical properties (such as melting points and solubilities) of materials containing these supramolecular synthons.

Keywords: crystal engineering, supramolecular synthon, ammonium carboxylates. 

Poster Sessions

on building units (Bus) consisting in oxo-centered O(BiM), tetrahedra sharing edges and surrounded by isolated phosphate groups. These 2D Bus are able to self-organise in versatile 3D regular intergrowths. A large number of intergrowths, with long Bus have been evidenced, rationalized and enabling the establishment of a method being able to predict hypothetic new materials [3].

In this work the prediction, formulation and synthesis of new phases with ribbons $n = 5, 8$ has been completed. The dielectric properties and SHG measurements of these non centrosymetric compounds will be presented. The mega-series corresponding to the intergrowths has been rationalized as a function of $n$ and fully applied to the synthesis of new materials. The figure 1 shows the design of a predicted structure with $n = 8$ and the structural verification by HREM.

Changing solid-state reaction stereochemistry: Heavy-Atom – co-crystal method
Reiko Kuroda, Ryo Sekiya, Department of Life Sciences, Graduate School of Arts and Sciences, The University of Tokyo (Japan). E-mail: ekuroda@mail.ecc.u-tokyo.ac.jp

Solid-state reactions exhibit high stereoselectivity compared with conventional solution reactions, but that cannot be generally altered as the origin of the selectivity is generally dictated by the molecular and crystal structures themselves[1], although in some cases they proceed in stages to give different products with time [2]. We have found that intramolecular photocyclization reaction of 2-(substituted-arylthio)-3-methyl-2-cyclohexenones (X(1), X(2), X(3)) isomers. Crystals X(2) and X(3) (X signifies crystal) are isomorphous to each other. Compound 3 in X(3) gave only the cis product, whereas 2 in X(2) gave both the trans and the cis isomers. 1 in X(1) gave only the trans product. Time course experiments have revealed that there are two reaction pathways; Path A and Path B. Path A is initiated by the photoexcited (trans-T*) state via an intersystem crossing from the (t-T*) state, which is the typical reaction path of photocyclization of cyclohexenones in solution. The reaction first produces the trans product which is converted to the cis-isomer slowly by proton abstraction by the carbonyl oxygen followed by keto-enol tautomerism. On the other hand, Path B is a newly found path in the solid state which produces the cis product directly, initiated most likely by the photoexcited (n-T*) state. Formation of cis products 2c and 3e from the beginning of the reaction cannot be explained by the trans-to-cis isomerisation, an intrinsically slow reaction.

X(1) adopts Path A, X(2) Path B, whereas X(2) both Path A and Path B. Solution reactions of 1, 2 and 3 all gave similar reaction products. Thus, the choice of reaction pathway is determined by the external heavy atom (H-A) effect in the crystal through spin-orbit coupling. This means that by placing molecules concerned under the different degree of influence of heavy atoms, we can switch the reaction pathways and hence product distribution. We could achieve this by making co-crystals of heavy-atom containing and non-containing analogues in various ratios (1:1, 9:1 and 1:9), and then carrying out photocyclization on them. Indeed, the reaction products have dramatically changed depending on the co-crystals of different stoichiometry. As being solid-state reactions, they are fast and free from by-products.

Inorganic-organic nanocomposite materials have been studied extensively in recent years because of the variety of interesting and useful properties associated with this family of compounds. The layered hybrids specifically the 2D (RNH$_2$)$_2$MX$_2$ and (NH$_3$RNH)$_2$MX$_2$ series, have shown good semiconduction, photocconductivity, photoluminescence and electro luminescent behaviour due to their inherent quantum well nature [1]. In essence, by taking an inorganic semiconductor material, and effectively intercalating organic amine cations into it, the materials' dimensionality is changed, and in so doing, too optical properties of the material. The features most greatly affected by a change in dimensionality is, firstly, the band structure i.e., the tuning of the band gap, secondly, the electron mobility of the compound, and thirdly and most importantly, the ability to confine the electron and hole orbit's (excitons), which drastically alters the materials recombination luminescence (Fig.1). A practical advantage of inorganic organic hybrids is that they self assemble and are easily solution processed into thin films, this has positive implications regarding cost and the ease of processability for further technological applications such as LCD's displays [1].

Previously published results show the binding energy of the excitons increase as the dimensionality is decreased i.e. from 3D to 2D and from 2D to 1D. However there is a much larger increase in the binding energy from 2D to 1D systems as seen in Fig.1. Here we report the structure and optical properties of 1D hybrids with the general formula (RN+)$^n$Pb$I_3$, in which we further investigate the tunability of the band structure, the large binding energy associated with the excitonic behavior, and charge transfer effects between wires and spacers [3-5].

Fig 1. The binding energy effect as displayed in (piperidinium)Pb$I_3$ wires where we see the 1s exciton absorption peak at 365nm and the resultant 600nm photoluminescence emission both at 77K.
