Transition metal-catalyzed ethylene oligomerisation typically produces a broad range of α-olefins. The development of α-olefins is an ongoing process [1] and recently the selective tetramerisation of ethylene to 1-octene was reported [2]. The evaluation of a large number of diphosphinoamine (PNP) ligands with various substituents on both N and P ligands reported that the predominant factor in the catalytic selectivity is the steric bulk on the central nitrogen atom compared to the basicity of the phosphine [3-7].

This study reports the synthesis of a range of PNP ligands with varying catalytic activity and selectivity and with a systematic variation of electro-steric properties of the N-substituents. A range of crystal studies were completed to further evaluate any correlations [8-9]. A comparison of the crystallographic data of these PNP ligands with the catalytic behaviour was made in an attempt to further understand this process, but also to provide more information for further catalyst design [10].

**Structural properties of various Copper(II) catalysts for oxidation catalysts**

T.J. Muller, G. Steyl, A. Roodt, Department of Chemistry, University of the Free State, Nelson Mandela Avenue, Bloemfontein, 9300, (South Africa). E-mail: Muller.Theunis@gmail.com

The aerobic oxidation of substituted phenols as a research topic plays an important role in synthesis and biological systems. The demand for value added derivatives of phenolic compounds is steadily growing in the world market, with benzoquinone derivatives constituting a key intermediate in the industrial production of Vitamin E. The use of dioxygen as oxidant is environmentally friendly and available in bulk from the atmosphere. Dioxygen can be catalytically activated by first row transition metal complexes (Cu(II), Co(II) and Mn(IV)). The addition of co-catalysts (LiCl or MgCl₂) can significantly increase the activity of these catalysts during the oxidation cycle.

In the current study, model catalyst precursors containing O,O bidentate ligand systems such as troplone and 2-methyl-3-hydroxy-4-pyrene derivatizes, which forms five-membered chelates, have been synthesized and structurally characterized, and will be discussed. Different aspects of the dioxygen oxidation of selected organic substrates by these copper(II) catalysts, as well as a proposed mechanism for the process, will also be presented.

**The role of crystallography in chemical kinetics and industrial processes**

Hendrik G. Visser, Andreas Roodt, Nicoline Cloete, Department of Chemistry, University of the Free State, Bloemfontein, (South Africa). E-mail: visserhg@ufs.ac.za

Single crystal crystallography plays a very important part in understanding the mechanisms of chemical reactions, including catalytic reactions. The isolation and identification of intermediates and products provide the researcher with a clearer understanding of reaction routes and the effects of steric bulkiness and/or electronic effects of coordination compounds.

**Coordinated productive and unproductive substrate binding in the COX-2 homodimer**

Alex J. Vechio, Michael G. Malkowski, The Hauptman-Woodward Medical Research Institute and Department of Structural Biology, The State University of New York at Buffalo, Buffalo, NY, (USA). E-mail: avecchio@hwi.buffalo.edu

The cyclooxygenases (COX-1 and COX-2) are membrane-associated heme-containing homodimers that generate prostaglandin H₂ from arachidonic acid (AA) in the committed step of prostaglandin and thromboxane biogenesis and are the targets for nonsteroidal anti-inflammatory drugs. Both isoforms behave as heterodimers during catalysis, exhibiting half-of-sites reactivity. Although AA is the preferred substrate for both COX isoforms, these enzymes, with varying efficiencies, oxygenate other fatty acid and endocannabinoid substrates. To elucidate the atomic level interactions that are involved with binding and conformational positioning of substrates for catalysis, we determined the X-ray crystal structures of AA, eicosapentaenoic acid (EPA), and 1-AG, bound in different conformations in each monomer constituting the homodimer in their respective structures, such that one monomer exhibits productive binding and the other unproductive binding of the substrate in the cyclooxygenase channel. Comparison of the COX-2: substrate crystal structures revealed an alternate rotamer conformation of Leu-531 that allowed for these novel substrate conformations; but substrate crystal structures revealed an alternate rotamer conformation of Leu-531 that allowed for these novel substrate conformations; but...
