The Effect of High-Pressure on Molecular Magnetism

Alessandro Prescimone,* Simon Parsons,* Euan K. Brechin,* Stephen Hill,† Stan Tozer,* ‡EaStCHEM School of Chemistry, Joseph Black Building, The King’s Buildings, Edinburgh, EH9 3JU, (UK). †National High Magnetic Field Laboratory 1800 E. Paul Dirac Drive, Tallahassee, FL 32310, (United States). E-mail: a.prescimone@ed.ac.uk

Polynuclear clusters of paramagnetic metal ions have attracted intense study since the discovery that such molecules can display the phenomenon of single-molecule magnetism [1]. The energy barrier to the relaxation of the magnetisation implies a large ground state spin multiplicity (S) and a significant zero-field splitting (D) of that ground state. The strength of coupling and the magnitude of the zero-field splitting are governed by the molecular geometry. Here we show that the application of hydrostatic pressure can significantly change the intra-molecular bond lengths and angles – and in some cases the connectivity - in a host of molecular or molecule-based complexes and in-so-doing greatly modify the observed magnetic parameters [2-7].

Two ‘Mn₄’ SMMs, hydroxo-bridged Cu dimers and Cu-based chains can all be structurally and magnetically distorted by pressure. We describe the combined high pressure crystallographic and high pressure magnetism and high pressure EPR experiments performed on these materials.

Structural studies of GaFeO₃ (SG Pcm₁) an antiferromagnetic (Tₘ=200 K) Mott insulator to 70 GPa, complemented by ⁵⁷Fe Mössbauer spectroscopy and resistance measurements at compression and decompression reveal a fascinating sequence of structures. Starting at ~25 GPa a new structure, an orthorhombic perovskite (Pbnm), is sluggishly formed followed by a V(P) drop of -5.4%. The complete formation of the perovskite occurs at 42 GPa. In the 0 – 35 GPa range Tₘ reaches 300 K and V(P) decreases by one-order of magnitude, later on, in the 50 - 57 GPa range, the electrical transport activation energy drops from 0.28 to 0.11 eV. At 50 GPa an isostructural transition is detected, characterized by a discontinuous drop of V(P) by ~3%. Mössbauer spectra reveal a non-magnetic component coexisting with the magnetic one at ~60 GPa. Its abundance increases and above 77 GPa no sign of a magnetic hyperfine interaction is detected down to 5 K. Concurrently, one observes a continuous yet precipitous decrease in R(P) taking place in the 58-68 GPa range, leading to an onset of the metallic state at P > 68 GPa. These electronic/magnetic features of the high pressure (HP) perovskite are consistent with a Mott transition (MT).

With pressure decrease, below 52 GPa, the insulating perovskite is recovered, and at 23 GPa a 1₄-order structural transition takes place to the LiNbO₃-type structure with R3c SG. This structure remains stable down to ambient pressure and with recompression it is stable up to 50 GPs, afterwards, it breaks back to the HP perovskite structure. It is noteworthy that this transition occurs at the same pressure, regardless of the preceding structures: Pbnm or R3c. The results are compared with hematite (Fe₂O₃ SG R3c) [1, 2] and other ferric oxides. The mechanisms of the transitions are discussed.

Structure and properties predictions for high-pressure crystal structures: Bi₃Mg, and Si

Dennis D. Klug, Yansun Yao, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6 E-mail: Dennis.Klug@nrc.ca

The recent rich diversity of diffraction studies on crystalline materials at high pressures has provided an opportunity for structural search methods based on first-principles methods to be employed for possible full characterization of structures. In this study, we report on our recent studies using several structure search methods including quasi-random searches, and the metadynamics technique as applied to systems where diffraction data provides a challenge to full characterization of structures. We will focus on several materials where excellent diffraction data has presented additional questions for a full knowledge of several high-pressure crystalline structures. We will use examples including our recent work on Bi₃Mg and Si.

A combination of structure search methods has, for example, been employed to predict the crystalline structure of Bi₃Mg that is agreement with the recently published diffraction data [1]. The use of a combination of methods is demonstrated to reveal the crystalline structure consisting of Bi₃Mg dimers as fundamental components that is most consistent with the diffraction data and reported properties such as phase transition pressures and metallization of this material.

Our investigation of the phase diagram of Mg addresses the question on phase transitions in this material. First-principles metadynamics and density functional methods were employed to investigate the temperature dependence of structural transitions in Mg. The phase identified as a double hexagonal close-packed phase and its location in the phase diagram of Mg at high pressure and temperature is
