The availability of intense and collimated synchrotron sources and fast-reading detectors, with the increased likelihood of severe radiation damage, has enabled and forced the community of protein crystallographers to acquire large numbers of datasets of a same structures in a relatively short interval of time. A similar speeding up will have to be built in the processing of such multiple sets, or data collection efforts go wasted. A computer program, BLEND, has been implemented for this task. BLEND uses multivariate statistics, mainly in the form of cluster analysis, to bring together datasets with better merging likelihood. The program allows researchers to save time both in avoiding the combinatorial explosion implied in the analysis of multiple datasets and in the cumbersome and time-consuming amount of bookeeping that goes with it. This talk will highlight BLEND's workings and illustrate its ability to carry out optimal selection of groups of datasets with several real-data examples.

BLEND is currently installed at the Diamond Light Source synchrotron, where an increasing number of users employ it to sift through their datasets. BLEND has been used successfully in the solution of a novel membrane protein.

Adams<sup>e</sup>, <sup>a</sup>Los Alamos National Laboratory, Mailstop M888, Los Alamos, NM 87545, USA, <sup>b</sup>University of Washington, Department of Biochemistry, Seattle, WA, 98195, USA, <sup>c</sup>University of Cambridge, Department of Haematology, Cambridge Institute for Medical Research, Cambridge, CB2 0XY, UK, <sup>d</sup>Stanford University, Departments of Molecular and Cellular Physiology, Neurology and Neurological Science, Structural Biology, Photon Science, and Howard Hughes Medical Institute, 318 Campus Drive West, Stanford, CA 94305-5432, <sup>e</sup>Lawrence Berkeley National Laboratory, One Cyclotron Road, Bldg 64R0121, Berkeley, CA 94720, USA E-mail: terwilliger@lanl.gov

Molecular replacement is an immensely powerful method for determining macromolecular crystal structures. The method nevertheless remains limited by the requirement for a template structure that is similar to the structure to be determined. Normally a template with an rmsd of core main-chain atoms of about 1.5-2 Å is required. The applicability of molecular replacement would be greatly expanded if templates differing from the target structure by 2 to 3 Å rmsd could routinely be used. Here we describe three new approaches for carrying out molecular replacement with distant homology models.

The first approach [1] combines the power of Rosetta structure modeling with Phenix automated molecular replacement, model-building, density modification, and refinement to yield a new general-purpose and easy-to-use tool for crystallographic structure determination. Molecular replacement (MR) solutions are obtained with phenix.automr, rebuilt with Rosetta including electron density map information, and then are further rebuilt with phenix.autobuild. The combination of Rosetta rebuilding and phenix rebuilding is the key part of this method. This combination merges the benefits of structure-modeling, in which homology models can now be created that are more accurate than the templates used to create them, with crystallographic structure determination and refinement, in which models are built that are consistent with measured crystallographic structure factors.

The second approach takes advantage of the observation that many pairs of proteins have local structures that can be superimposed much more closely than can their complete structures. For example, a  $\beta$ -sheet in one protein may be locally similar to a sheet in another, but when the two structures are superimposed using all atoms, the sheets may be translated relative to each other. We have developed a method for applying local distortions to a structure (morphing it) using an electron density map to guide the distortions. This procedure allows local similarity to be maintained while global structure is changed. We show that morphing molecular replacement templates after placing them in their approximate locations in the crystallographic unit cell can greatly improve subsequent model-building.

The third approach is a combination of DEN (deformable elastic network) refinement and phenix.autobuild [2]. DEN refinement is also a general and easy-to-use tool for structure determination of difficult structures, especially for cases with low-resolution diffraction data and/or data with significant anisotropy. DEN-refinement allows local structure to be retained during refinement while secondary structural elements can undergo deformations and large regions such as domains can be shifted substantially. DEN refinement can be combined with morphing and autobuilding to yield a powerful combined approach to model rebuilding. It is available in the Crystallography and NMR System (CNS) v1.3, and will also be available in phenix.refine in the near future.

The Phenix software (including phenix.mr\_rosetta and phenix.morph\_model) is available at http://www.phenix-online.org and Rosetta is available at http://depts.washington.edu/uwc4c/ express-licenses/assets/rosetta.

**MS4-02** Classical-style MAD phasing with wavelength interleaving and kappa goniometry on PROXIMA-1. <u>Gérard Bricogne</u><sup>a</sup>, Clemens Vonrhein<sup>a</sup>, Peter Keller<sup>a</sup>, Andrew Thompson<sup>b</sup>, Pierre Legrand<sup>b</sup>, Christian Cambillau<sup>c</sup>, Silvia Spinelli<sup>c</sup>, Svetlana Antonyuk<sup>d</sup>, Martyna Pastok<sup>d</sup>, Paul Elliott<sup>d</sup> <sup>a</sup>Global Phasing Ltd, Cambridge, United Kingdom, <sup>b</sup>Synchrotron SOLEIL, Gif sur Yvette, France, <sup>c</sup>AFMB, Campus de Luminy, Marseille, France, <sup>d</sup>Institute of Integrative Biology, The University of Liverpool, United Kingdom. E-mail : gb10@globalphasing.com

In the early days of the MAD method, Hendrickson et al. (see e.g. [1]) used carefully designed protocols to maximise the signal-to-noise (S/N) ratio of anomalous and dispersive signals. Optimal anomalous S/N was achieved by re-orienting crystals on a multi-axis goniometer to record Bijvoet pairs on the same image, or by the interleaving of thin wedges (typically, 5 to 10 degrees) of data collected 180 degrees apart in rotation angle ("inverse-beam" method). High-S/N dispersive differences were obtained by similarly interleaving thin wedges of data at inflection-point and remote wavelengths. The special accuracy of these phasing differences was then exploited via the MADSYS software suite [2]. The advent of third-generation synchrotron sources and of CCD detectors created strong pressure towards data collection strategies that would be devoid of the complications of inverse-beam and wavelength-interleaving protocols, after it was shown that simpler strategies involving the collection of full datasets, for one wavelength at a time, around a single axis, were capable of yielding MAD-phased structures in remarkably short times [3]. From that point on, although many beamline GUIs still offered their users options to program inverse-beam and/or wavelength-interleaved experiments, these protocols rapidly fell into disuse except in the hands of a few devotees. We have revisited the original complex protocols with modern approaches to data processing, substructure solution and phasing (in particular the Bayesian approach to phasing implemented in SHARP [4]) and assessed the gains in phasing power provided by these protocols over the conventional ones. Our studies have been performed mostly on structures phased experimentally by anomalous scattering effects at the Tantalum L-III edge. Besides presenting our specific results, we will discuss prospects for implementing these protocols and the associated processing and phasing procedures in the form of integrated workflows suitable for the modern context of high-speed beamline operation and requiring little or no expertise from the users.
